AB We have chosen E. coli K92, which produces the alternating structure alpha (2-8) neuNAc alpha (2-9) neuNAc as a model system for studying bacterial polysaccharide biosynthesis. We have shown that the polysialyltransferase encoded by the K92 neuS gene can synthesize both alpha (2-8) and alpha (2-9) neuNAc linkages in vivo by C-13-nuclear magnetic resonance analysis of polysaccharide isolated from

heterologous strain containing the K92 neuS gene. The K92 polysialyltransferase is associated with the membrane in lysates of cells harboring the neuS gene in expression vectors. Although the enzyme can transfer sialic acid to the nonreducing end of oligosaccharides with either linkage, it is unable to initiate chain synthesis without exogenously added polysialic acid. Thus, the polysialyltransferase encoded by neuS is not sufficient for de novo synthesis of polysaccharide but requires another membrane component for initiation. The acceptor specificity of this polysialyltransferase was studied using sialic acid oligosaccharides of various structures as exogenous acceptors. The enzyme can transfer to the nonreducing end of all bacteria polysialic acids, but has a definite preference for alpha (2-8) acceptors. Gangliosides containing neuNAc oc(2-8)neuNAc are elongated, whereas monsialylated gangliosides are not. Disialylgangliosides are better acceptors than short

oligosaccharides, suggesting a lipid-linked oligosaccharide may be preferred in the elongation reaction. These studies show that the K92 polysialyltransferase catalyzes an elongation reaction that involves transfer of sialic acid from CMP-sialic acid to

nonreducing end of two different acceptor substrates.

AB The invention presents the recombinant prodn. of gene neuS.alpha.2,8/2,9-

polysialyltransferase from Escherichia coli K92. The invention provides plasmid vectors contg. the neuS gene, host cells transformed with said vectors, and processes involved in obtaining the purified recombinant .alpha.2,8/2,9-polysialyltransferase. The invention also provides methods used to show that E. coli K92 .alpha.2,8/2,9-polysialyltransferase is a functional enzyme able to convert a substrate to product. The invention specifically demonstrated PCR-based cloning of the E. coli neuS gene. A 1.2-kb PCR fragment was subcloned in pRSET vector and the protein was expressed in the BL21(DE3) strain of E. coli with a hexameric histidine at its N-terminal end. Western blotting using anti-histidine antibody showed

presence of a band that migrated at about 47.5 kD on both reducing and non-reducing SDS-PAGE, indicating a monomeric enzyme. Among the carbohydrate acceptors tested, N-acetylneuraminic acid and the gangliosides GD3 and GQ1b were preferred substrates. The cell-free enzyme

reaction products obtained were characterized by NMR and mass spectrometry, which indicated the presence of both .alpha.2,9- and .alpha.2,8-linked polysialyl structure. The K92 neuS gene was used to transform the K1 strain of E. coli, the capsule of which contains only (-8-NeuAc.alpha.2-) linkages. Anal. of the polysaccharides isolated from these transformed cells is consistent with the presence of both (-8-NeuAc.alpha.2-) and (-9-NeuAc.alpha.2-) linkages, thus supporting

E. coli K92 catalyzes the synthesis of polysialic acid with .alpha.2,9-and .alpha.2,8- linkages.

The capsular polysaccharide of Escherichia coil K92 contains AΒ alternating -8-NeuAc alpha 2- and -9-NeuAc alpha 2- linkages. The enzyme catalyzing this polymerizing reaction has been cloned from the genomic DNA

of E. coil K92. The 1.2-kilobase polymerase chain reaction fragment was subcloned in pRSET vector and the protein was expressed in the BL21(DE3) strain of E. coli with a hexameric histidine at its N-terminal end, The enzyme was isolated in the supernatant after lysis of the cells and fractionated by ultracentrifugation. Western blotting using

anti-histidine

antibody showed the presence of a band that migrated at about 47.5 kDa on both reducing and nonreducing SDS-polyacrylamide gel electrophoresis, indicating a monomeric enzyme. Among the carbohydrate accepters tested, N-acetylneuraminic acid and the gangliosides G(D3) and G(Q1b) were preferred substrates. The cell-free enzyme reaction products obtained

were

characterized by NMR and mass spectrometry, which indicated the presence of both alpha 2,9- and alpha 2,8-linked polysialyl structure. The K92 neuS

gene was used to transform the K1 strain of E. coil, the capsule of which contains only -8-NeuAc alpha 2- linkages. Analysis of the polysaccharides isolated from these transformed cells is consistent with the presence of both -8-NeuAc alpha 2- and -9-NeuAc alpha 2- linkages. Our results

that the neuS gene product of E. coil K92 catalyzes the synthesis of polysialic acid with alpha 2,9- and alpha 2,8-linkages in vitro and in vivo.

Haemophilus ducreyi, the cause of the sexually transmitted disease AB chancroid produces a lipooligosaccharide (LOS) containing a terminal sialyl N-acetyllactosamine trisaccharide, Previously, we reported the identification and characterization of the N-acetylneuraminic acid cytidylsynthetase gene (neuA), Forty-nine base pairs downstream of the synthetase gene is an open reading frame (ORF) encoding a protein with a predicted molecular weight of 34,646, This protein has weak homology to the polysialyltransferase of Escherichia colt K92, Downstream of this ORF is the gene encoding the H, ducreyi homologue of the Salmonella typhimurium rmlB gene. Mutations were constructed in the neuA gene and the gene encoding the second ORF by insertion of an Omega kanamycin cassette, and isogenic strains were constructed. LOS was isolated from each strain and characterized by SDS-polyacrylamide gel electrophoresis, carbohydrate, and mass spectrometric analysis, LOS isolated from strains containing a mutation in neuA or in the second ORF, designated Ist, lacked the sialic acid-containing glycoform, Complementation studies were performed, The neuA gene and the ist gene were each cloned into the shuttle vector pLS88 after polymerase chain reaction amplification. Complementation of the mutation in the ist gene was observed, but we were unable to complement the neuA mutation, Since

it

is possible that transcription of the neuA gene and the Ist gene were coupled, we constructed a nonpolar mutation in the neuA gene, in this construct, the neuA mutation was complemented, suggesting transcriptional coupling of the neuA gene and the ist gene, Sialyltransferase activity

was

detected by incorporation of C-14-labeled NeuAc from CMP-NeuAc into trichloroacetic acid-precipitable material when the Ist gene was overexpressed in the nonpolar neuA mutant. We conclude that the Ist gene encodes the H, ducreyi sialyltransferase, Since the Ist gene product has little, if any, structural relationship to other sialyltransferases, this protein represents a new class of sialyltransferase.

LANGUAGE: English

AB Polysialic acids are synthesized by pathogenic bacteria as capsular polysaccharides. These polymers have been implicated in the virulence of some strains of Escherichia coli which cause neonatal meningitis and urinary tract infections. There has been significant progress in identifying the gene necessary for capsular polysaccharide biosynthesis in gram neg. bacteria. Much of the enzymol. of polysialic acid capsular polysaccharide synthesis has been done with the a-(2-8)polysialyltransferase complex of E.coli K1. Bacteria contg. DNA fragments encoding several capsule related genes have been used as a

source of enzyme activity. As a model system for investigating the mechanism of caps or glycosyltransferases we have osen to investigate the K92 a(2-8)(2-solysialyltransferase in a general

background lacking other capsule related genes. The K92 PST requires an exogenously added acceptor when assayed in this genetic background. The K92 polysialyltransferase does not require neuE gene

product for activity. The effect of acceptor repeat unit structure,

chain

lenght on elongation activity was detd. by the addn. of other sialic acid polymers, oligosialic acid, and gangliosides.

AB Polysialic acids occur as capsular polysaccharides of several pathogenic bacteria. An understanding of how polysialyltransferase functions in the synthesis of polysialic acid will require enzyme purification and characterization in concert with genetic analysis. A rapid filter assay has been developed for bacterial polysialyltransferase suitable for enzyme purification. The filter assay and the currently used paper chromatography methods are equivalent in parallel experiments. The Escherichia coli K92 polysialyltransferase exhibited the same pH and temperature

optima, Mg2+ dependence and acceptor specificity in both assays.

[C-14] Sialic acid bound in filter assays correlates with polymer formed by

gel filtration. Specificity may be increased by the addition of exogenous accepters.

LANGUAGE:

A genetic system was developed to investigate the mol. mechanisms of .alpha.2,8-linked polysialic acid (PSA) capsule synthesis, translocation, and regulation in the neuroinvasive bacterium E. coli K1. The 12 to 14 genes required for these processes are located in a multigenic kps

cluster

at chromosome unit 64. The cluster is composed of a central group of biosynthetic neu genes (region 2) that are flanked on either side by region 1 or 3 kps genes encoding general functions for PSA regulation, assembly, and translocation. The polysialyltransferase (polyST) encoded by K1 neuS was sequenced and compared to its homolog in K92 E. coli, which synthesizes PSA chains with alternating sialyl .alpha.2,8-2,9 linkages. The results indicate that polySTs are

processive

enzymes which catalyze sequential transsialylations from donor CMP-sialic acid mols. to the nonreducing end of nascent PSA chains. The authors propose that the polymerase functions in a complex that includes the region 2 gene product of neuE and region 1 and 3 gene products of kpsMTSCDE. NeuE appears to function in the initiation or termination of PSA synthesis and may interact with polyprenol, as suggested by a dolichol-like binding site located in its predicted C-terminal membrane-spanning domain. These conclusions are supported by phenotypic anal. of mutants with multiple defects in sialic acid synthesis, degrdn., and polymn.

\*ABSTRACT IS AVAILABLE IN THE ALL AND IALL FORMATS\* AB

The neuS-encoded polysialyltransferase (polyST) in Escherichia coli K1 catalyzes synthesis of polysialic acid homopolymers composed of unbranched sialyl-alpha-2,8 linkages: Subcloning and complementation experiments showed that the K1 neuS was functionally interchangeable with the neuS from E. coli K92 (S. M. Steenbergen, T. J. Wrona, and E. R. Vimr, J. Bacteriol. 174:1099-1108, 1992), which synthesizes polysialic acid capsules with alternating sialyl-alpha-2,8-2,9 linkages. To better understand the relationship between these polySTs, the complete K92 neuS sequence was determined. The results demonstrated that K1 and K92 neuS genes are homologous and indicated that the K92 copy may have evolved from its K1 homolog. Both K1 and K92 structural genes comprised 1,227 bp. There were 156 (12.7%) differences between the two sequences; among these mutations, 55 did not affect the derived primary structure of K92 polyST and hence were synonymous with the K1 sequence.
Assuming maximum simony, another estimated 17 sequence.

plus

84 nonsynonymous mutations could account for the 70 amino acid replacements in K92 polyST; 36 of these replacements were judged to be conservative when compared with those of K1 polyST. There were no changes detected in the first 146 5' or last 129 3' bp of either gene, suggesting, in addition to the observed mutational differences, the possibility of a past recombination event between neuS loci of two different kps clusters. The results indicate that relatively few amino acid changes can account for the evolution of a glycosyltransferase with novel linkage specificity.

The polysialyltransferase (polyST) structural gene, neuS, for poly-alpha-2,8sialic acid (PSA) capsule synthesis in Escherichia coli K1 was previously mapped near the kps region 1 and 2 junction (S. M. Steenbergen and E. R. Vimr, Mol. Microbiol. 4:603-611, 1990). Present Southern and colony blot hybrization results confirmed that neuS was a region 2 locus and indicated apparent homology with neuS from E. coli K92, bacteria that synthesize a sialyl-alpha-2,8-2,9-linked polymer. A K1- mutant with an insertion mutation in neuS was complemented

in trans by **K92** neuS, providing direct evidence that neuS encoded the PSA polymerase. A 2.9-kb E. coli K1 kps subclone was sequenced to better characterize polyST. In addition to neuS, the results

identified a new open reading frame, designated neuE, the linker sequence between regions 1 and 2, and the last gene of region 1, kpsS. The kpsS translational reading frame was confirmed by sequencing across the junction of a kpsS'-lacZ+ fusion. PolyST was identified by maxicell analysis of nested deletions and coupled in vitro transcriptiontranslation assays. PolyST's derived primary structure predicted a 47,500-Da basic polypeptide without extensive similarity to other known proteins. PolyST activity was increased 31-fold and was membrane localized when neuS was cloned into an inducible expression vector, suggesting, together with the polyST primary structure, that polyST is a peripheral inner membrane glycosyltransferase. However, polyST could not initiate de novo PSA synthesis, indicating a functional requirement for other kps gene products. The existence of a sialyltransferase distinct from polyST was suggested by identification of a potential polyprenyl-binding motif in a C-terminal membrane-spanning domain of the predicted neuE gene product. Direct evidence for a quantitatively minor sialyltransferase activity, which could function to initiate PSA synthesis, was obtained by phenotypic analysis of mutants with multiple defects in sialic acid synthesis, degradation, and polymerization. results provide an initial molecular description of K1 and K92 sialyltransferase complexes and suggest a possible common function for accessory kps gene products.
